Los Alamos, New Mexico

Outline

- SARS and its epidemiology
- A mathematical model for SARS
- The dynamics of SARS in Toronto, Hong Kong and Singapore
- Estimates of the basic reproduction number for SARS
- Comparison of the reproduction number with that of seasonal and pandemic influenza
- Conclusions

SARS

- **Severe acute Respiratory Syndrome** (SARS) is a new respiratory disease which was first identified in Guangdong's province of China.
- The outbreak of SARS was first identified in Vietnam by Dr. Carlo Urbani, a WHO expert in communicable diseases who succumbed to the disease.
- The causative agent of SARS is a new coronavirus (Drosten et al. And Ksiazek et al. 2003)
- WHO for the first time in history issued a global warning about the disease in March 2003.

Coronavirus from SARS isolated in FRhK-4 cells. Department of Microbiology, The University of Hong Kong and the Government Virus Unit.

The public image of SARS in Hong Kong

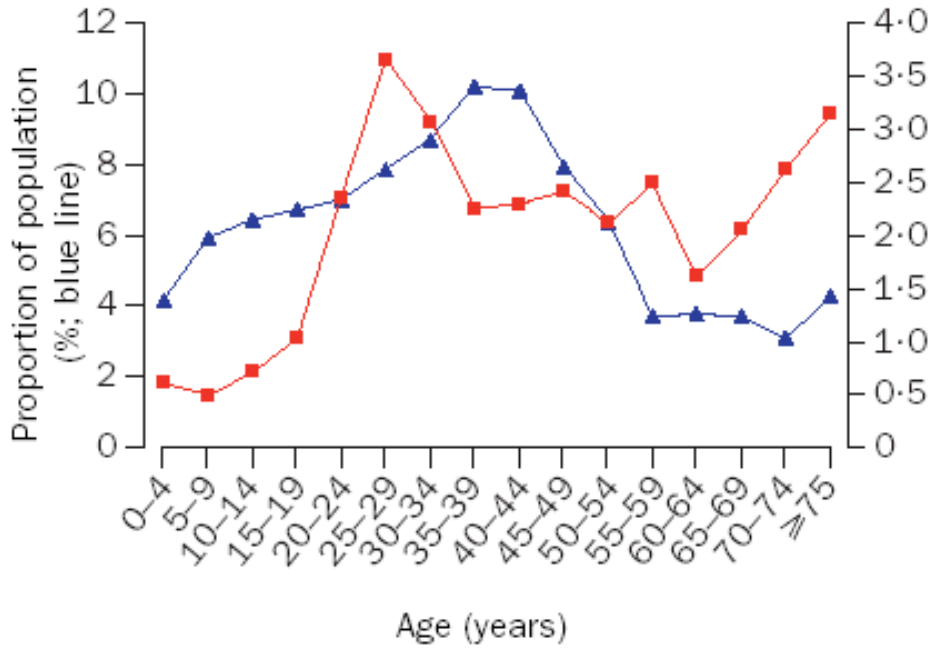
Epidemiology of SARS

- SARS is believed to be transmitted by close contact with an infectious individuals (droplets).
- An individual exposed to SARS may become infectious after an incubation period of 2-7 days.
- Infectious individuals experience similar symptoms to pneumonia including high fever, shortness of breath, dry cough, headache, stiff or achy muscles, fatigue and diarrhea.
- Most infected individuals recover typically after 7-10 days.
- The case fatality rate for patients younger than 60 years is 13.2% while for patients ages 60 or older is 43.3%.

Modeling the transmission dynamics of SARS

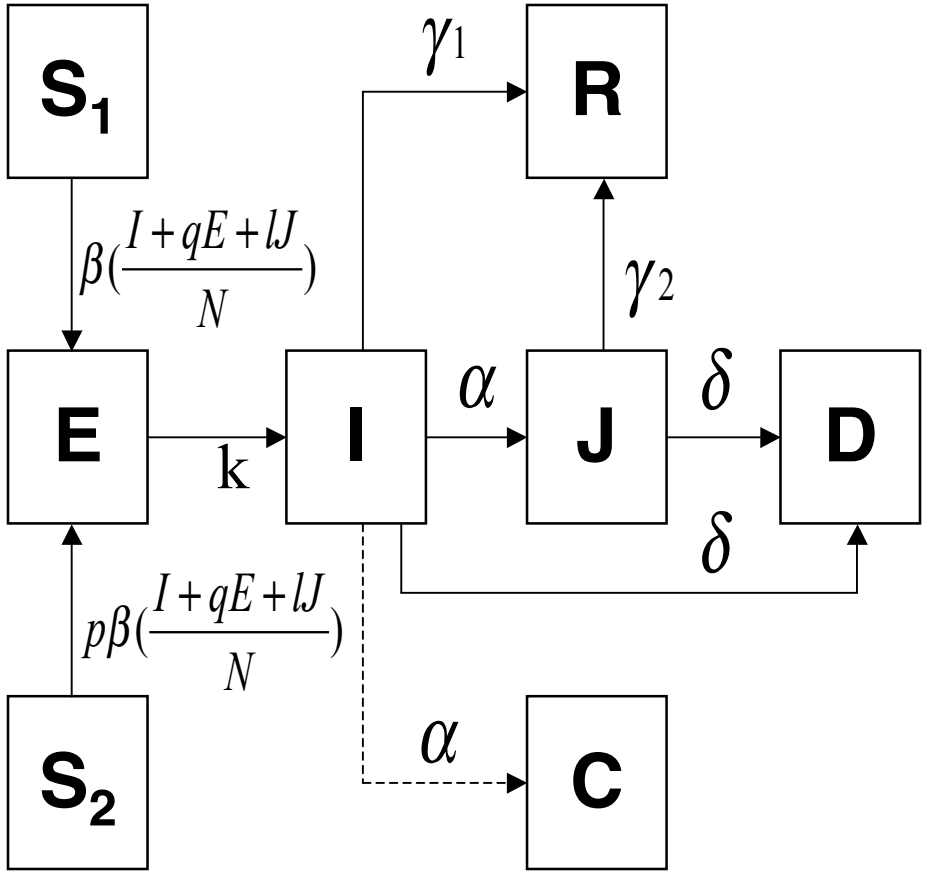
- To account for differences in susceptibility in the population, we introduce two susceptibles classes: S_1 and S_2. S_1 is the most susceptible class and S_2 is less so. For the case of Hong Kong, this can be illustrated with the following graph:

Age distribution of residents in Hong Kong (blue) and age-specific SARS incidence (red). Donnelly et al. (2003)



Compartmental model

- **E** (exposed). Asymptomatic, possibly infectious individuals.
- **I** (infectious). Infected, symptomatic not yet diagnosed individuals.
- **J** (diagnosed). Diagnosed (hospitalized) individuals.
- **R** (recovered). Individuals who recovered from the disease.
- **D** (dead). Individuals who died from the disease.



Chowell et al. (2003), Lipsitch et al. (2003), Riley et al. (2003), **Gumel et al. (2004), Lloyd-Smith (2004), Hsie et al. (2004).**

Parameter definitions and estimates

Parameter definitions and values that fit the cumulative number of "diagnosed" cases for Hong Kong.

Parameter	Definition	Value
β	Transmission rate per day	.75
q	relative measure of infectiousness for the asymptomatic class E	0.1
l	relative measure of reduced risk among diagnosed SARS cases	0.38
p	reduction in risk of SARS infection for class S_2	0.1
k	rate of progression to the infectious state per day	$\frac{1}{3}$
α	rate of progression from infective to diagnosed per day	$\frac{1}{3}$
γ_1	rate at which individuals in the infectious class recover per day	$\frac{1}{8}$
γ_2	rate at which diagnosed individuals recover per day	$\frac{1}{5}$
δ	SARS-induced mortality per day	0.006
ρ	Initial proportion of the popualtion at higher risk of SARS infection	0.4

Intervention measures

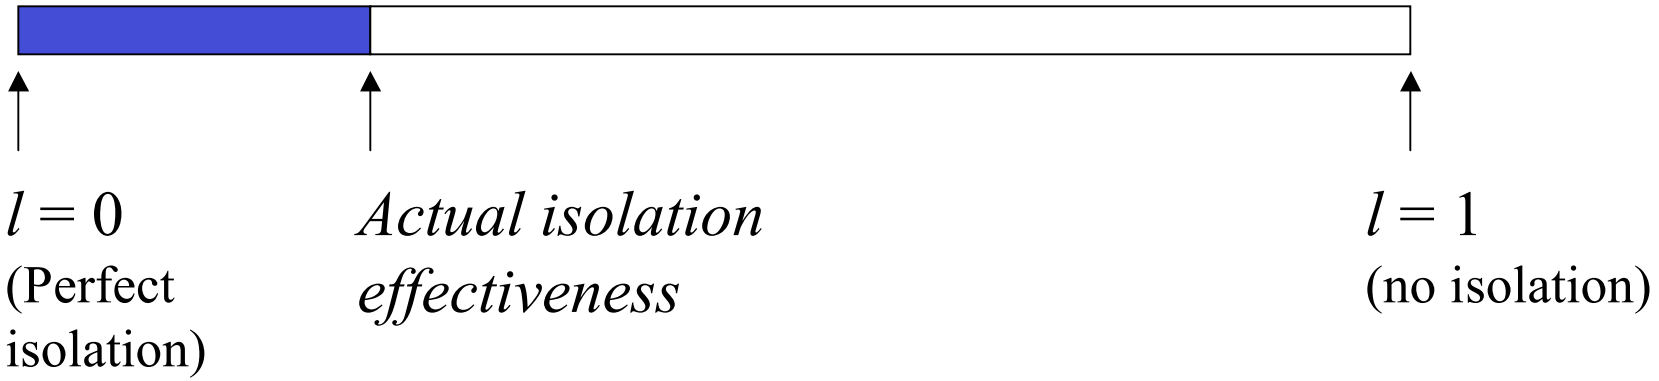
The image of SARS in hospitals

- Rapid diagnosis of patients
- Strict isolation procedures

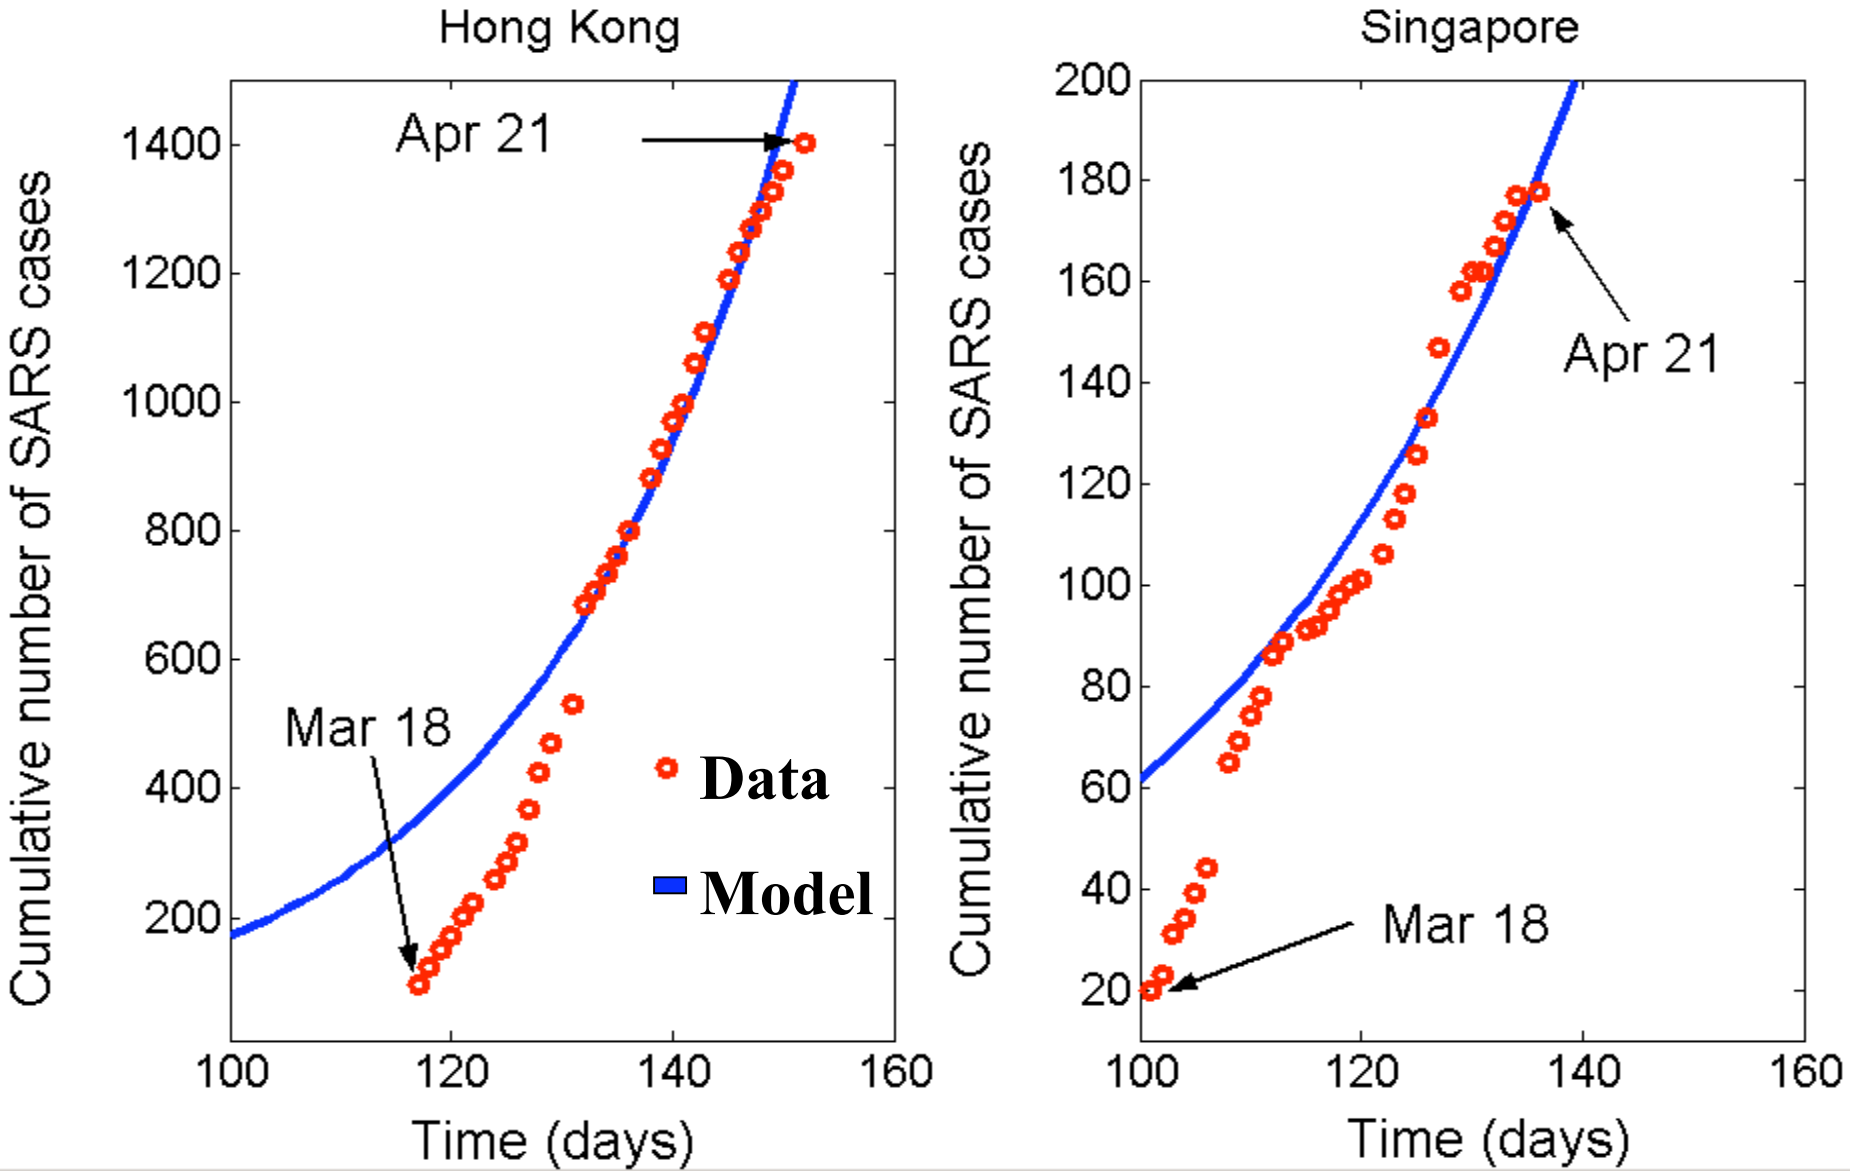
Before	***After***
Diagnostic period ~ 6 days	Diagnostic period ~ 3 days
Infectious individuals were not being properly isolated in hospitals	Isolation effectiveness was roughly 10 times better!

Isolation effectiveness (l)

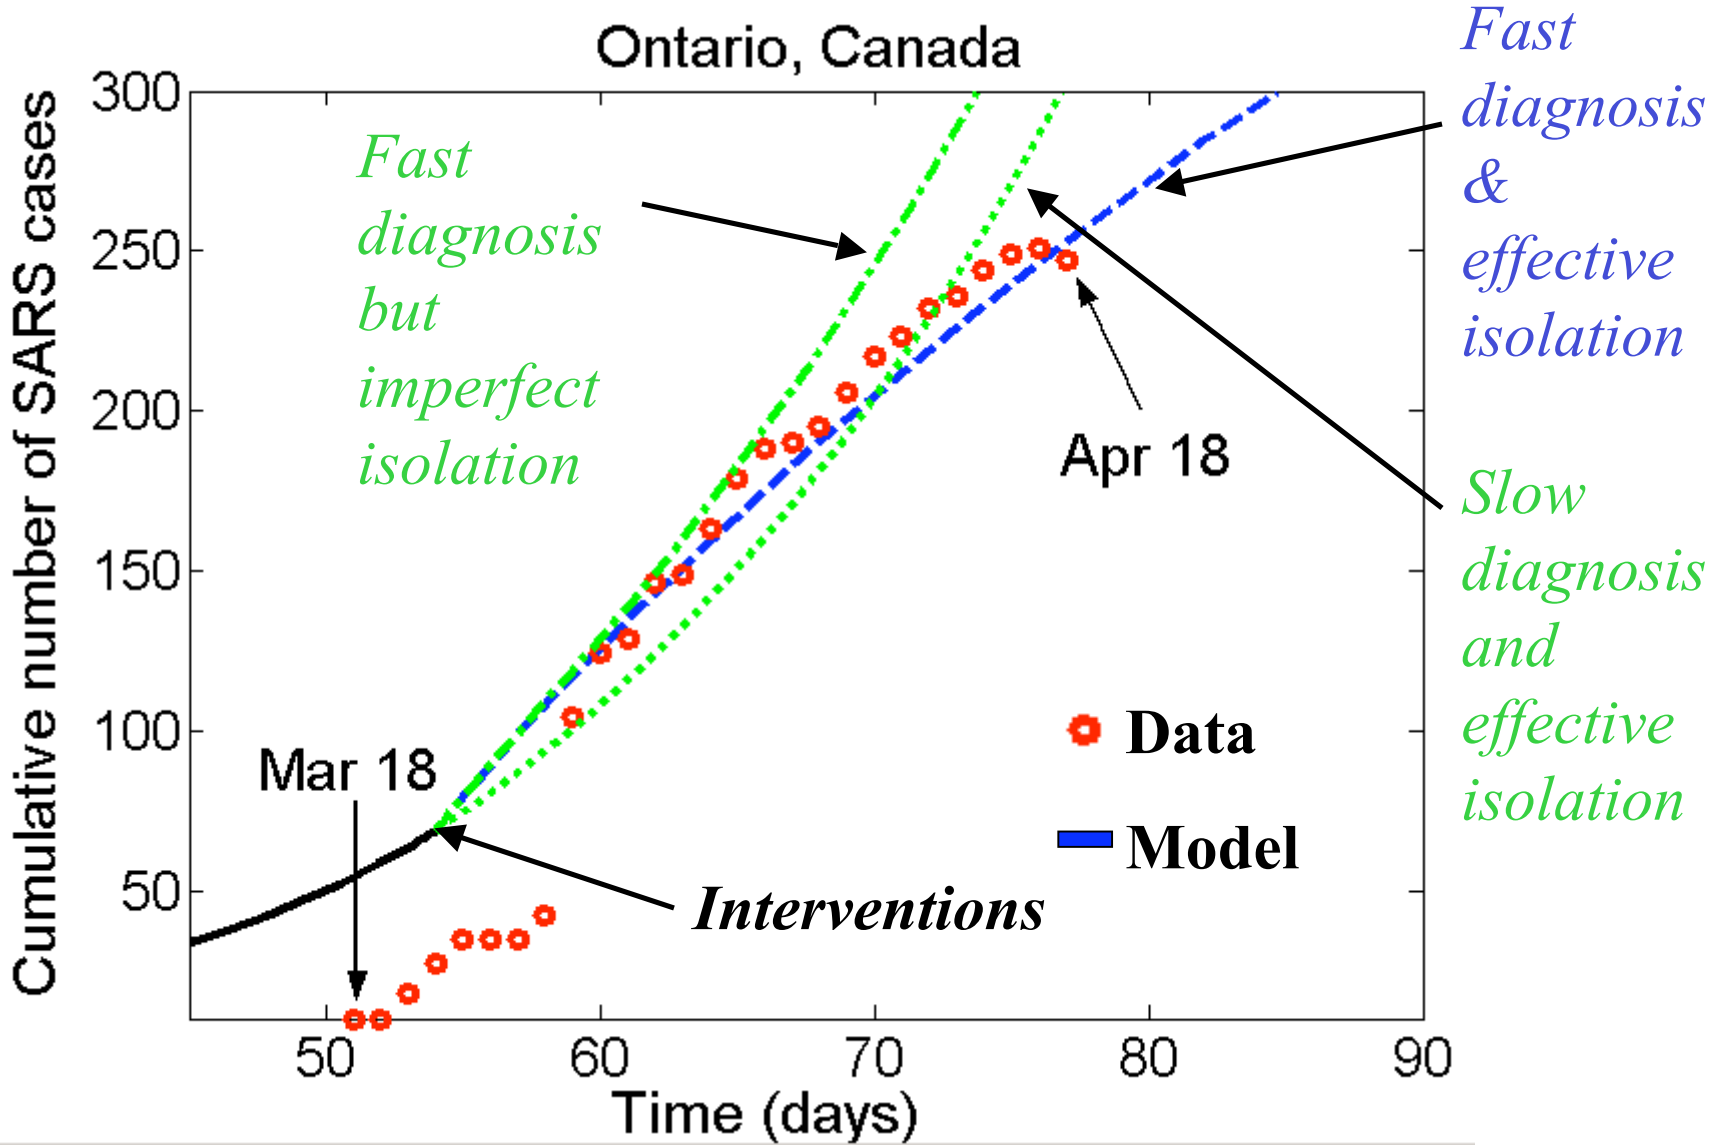
- $0 < l < 1$ is a measure of the effectiveness of the isolation procedures implemented in hospital wards (i.e appropriate nursing-barrier techniques, etc.)
- 94% of SARS cases in Taiwan occurrred in hospital wards.



The cases of Hong Kong and Singapore



The case of Toronto



The Basic reproduction number R_0

The number of secondary cases generated by a primary infectious case during its period of infectiousness in an entirely susceptible population is known as the **basic reproduction number R_0**.

A more practical quantity is the **reproduction number (R)** which measures the transmissibility in a partially immune population, where a fraction of individuals is effectively protected against infection before the start of the epidemic, because of residual immunity from previous exposure to influenza, or vaccination. For example, if a proportion p of a completely susceptible population is successfully immunized prior to an epidemic, the relation between the basic and the effective reproductive number is $R = (1\text{-}p)\ R_0$.

R_0 for SARS

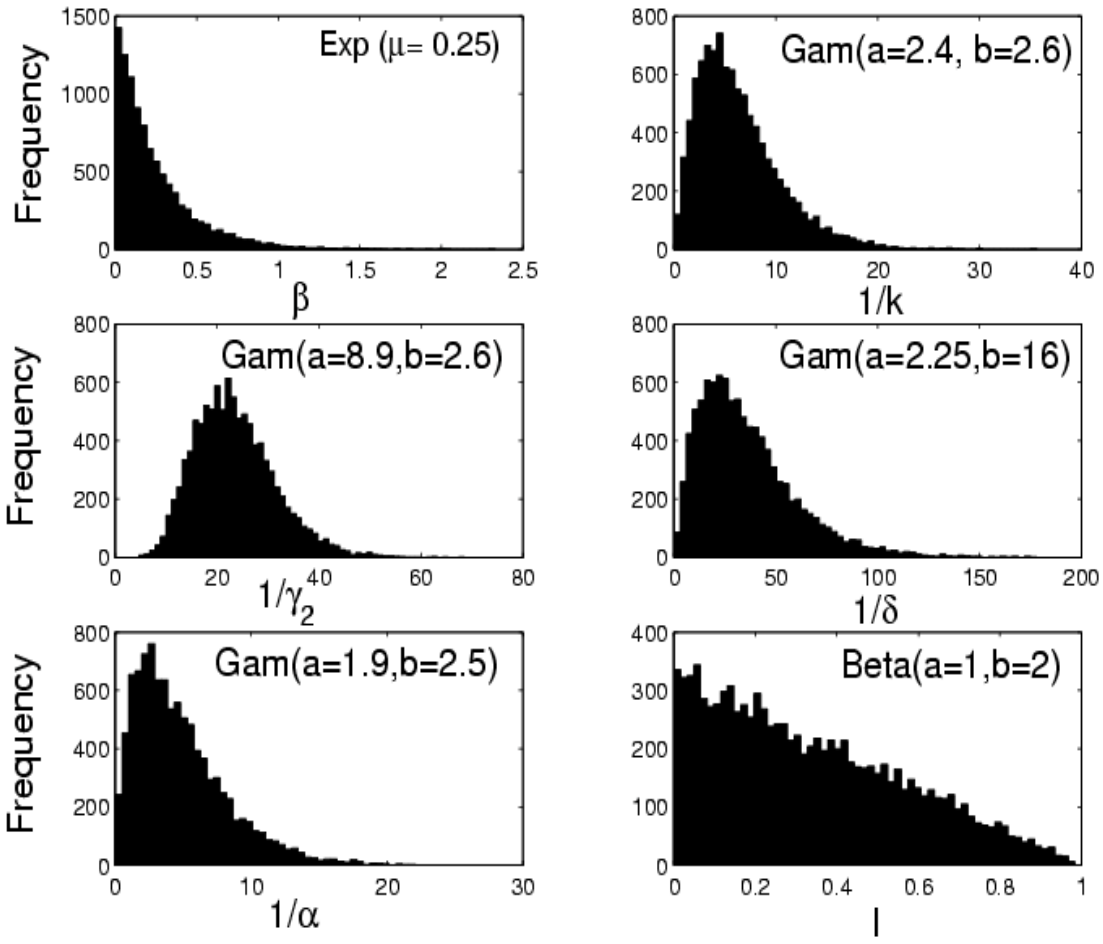
- Following the second generation approach (Diekmann and Heesterbeek, 2000), we can obtain the following expression for the basic reproductive number:

$$\mathcal{R}_0 = \{\beta\,[\rho + p(1-\rho)]\}\left\{\frac{q}{k} + \frac{1}{\alpha+\gamma_1+\delta} + \frac{\alpha l}{(\alpha+\gamma_1+\delta)(\gamma_2+\delta)}\right\}$$

- For Hong Kong $R_0 = 1.2$ and $R_0 = 1.1$ for Singapore.

Uncertainty analysis for R_0

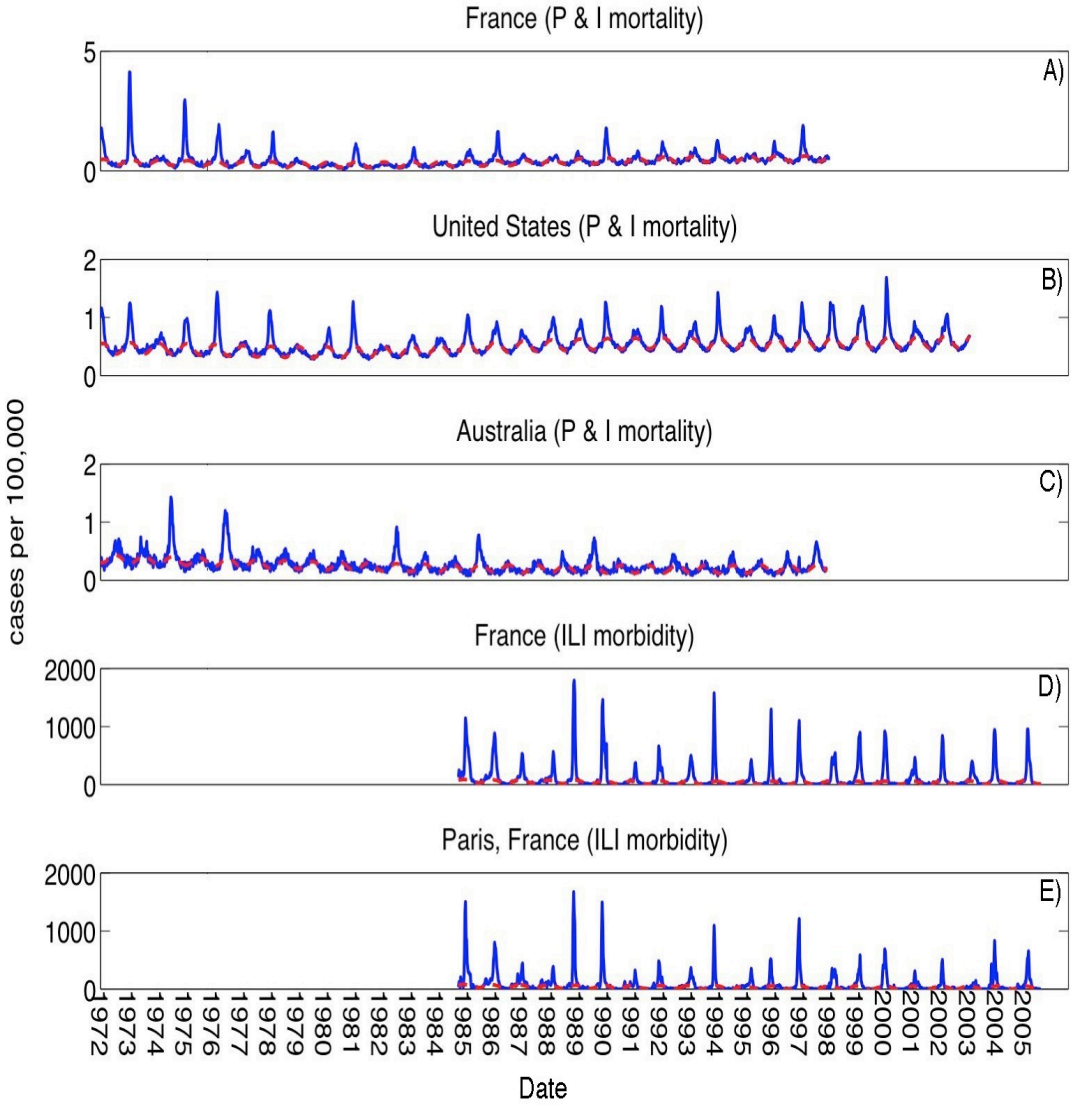
Parameter distributions (Donnelly et al. 2003)



Chowell, Castillo-Chavez, Fenimore, Kribs-Zaleta, Arriola, Hyman, Emerging Infectious Diseases (2004).

- For Hong Kong, R_0 = 1.8 (0.5, 2.5) and R_0 = 1.7 (0.4, 2.3) for Singapore.
- Under perfect isolation, 25% of the R_0 distribution lies at $R_0 > 1$. This highlights the importance of simultaneously applying more than one method of control.
- Lipstich et al. (2003), Riley et al. (2003) R0 ~ 2-3, assuming an exponential epidemic growth phase (may overestimate initial growth rate, Razum et al. 2003).

Seasonal influenza



- We find similar average reproduction numbers for inter-pandemic influenza in the three countries: 1.3 in the US (95% Confidence Interval (CI) 1.2-1.4), [Wilcoxon test for between country differences, $P>0.87$].

- Estimates of the reproduction number using morbidity data for France and the greater Paris area are in close agreement with those obtained using mortality data.

Conclusions

• A model that considers the effect of average infectiousness in an heterogeneous population has been introduced to explore the role of patient isolation and diagnostic rate in controlling a SARS outbreak.

• By examining two cases with relatively clean exponential growth curves we are able to calibrate the SEIJR model. We then use our SEIJR model to study the non-exponential dynamics of the Toronto Outbreak where the rapid slowing in the growth of new recognized cases, robustly constrain the SEIJR model by requiring that $l \approx 0.05$ and $\alpha > 1/3$ days^{-1}.

• The fitting of data shows that initial rates of SARS growth are quite similar in most regions leading to mean estimates of R_0 1.7-1.8

Conclusions, cont'

• In our model "good control" means (a) *at least* a factor of 10 reduction in *l* (effectiveness of isolation) and (b) simultaneously a *maximum* diagnostic period of 3 days. The model is sensitive to these parameters, so they should be treated as absolutely minimal requirements: better is better.

• The reproduction number of the Spanish Flu pandemic is approximately twice larger than that of seasonal flu ($R \sim R_0$).

• The reproduction number of the first (herald) pandemic wave is in agreement with that of seasonal flu.
